1 Introduction

1.1 Problem Background

Stairs are a common architectural element in our daily lives and an indispensable part of architectural history. From modern buildings to ancient temples and churches, stairs are often found and serve as records of human history. However, as time passes, the surface of stairs gradually develops uneven wear due to long-term use. These wears not only reflect how often and how the stairs were used, but also contain information about when they were built and the materials used, providing archaeologists with important clues about the history of the building.

Despite the important research value of stair wear, there are still relatively few targeted and systematic studies. Up to now, most analyses rely on qualitative observations and lack an analytical framework that can quantify wear patterns and their effects. To fill this research gap, there is an urgent need to develop mathematical models that combine the wear characteristics of stairs with information on foot traffic frequency, weight distribution, and environmental factors.

As shown in Fig. n, the wear traces of stairs exhibit complex and diverse patterns. Combining these features, the goal of our article is to provide archaeologists with a feasible measurement method and quantitative analysis of stair wear by building a mathematical model to excavate the historical and cultural information in the wear of stairs.

1.2 Restatement of the Problem

The wear of stairs is a complex object of study influenced by multiple factors combined. By analyzing the background of the problem in depth and combining the specific constraints, the problem can be restated as follows:

- **Problem 1:** Clarify the data requirements Under the assumption that archaeologists can employ low-cost, simple, and non-destructive measurements, clarify the key types of data that need to be acquired.
- **Prpblem 2:** Build an analytical model Build a mathematical model to analyze the wear of stairs and predict how the target stairs will be used, using the key data types acquired in Problem 1. Specifically include:
 - A. the frequency of use of the staircase;
 - B. the direction in which the stairs are primarily used (upward or downward preference);
 - C. the number of people using the stairs simultaneously and their mode of use (e.g., side-by-side walking or single-passing).
- **Problem 3:** Further exploration of issues related to specific conditions
Based on the..... model, provided being able to estimate the age exists, clarifying the way the stairwell was used, and understanding the daily pattern of life in the structure, analyse the following aspects in depth:

- D. whether the wear patterns are consistent with the available information;
- E. the estimation of the age of the stairs and its reliability;
- F. the repair or renovation history of the stairs;
- G. the certainty of the source of materials used in the construction of the stair;
- H. The information that can be determined includes the number of people using the stairs on a typical day and the usage frequency (whether it involves a large number of people over a short time or a small number over a longer period).

1.3 Our Work

2 Assumptions and Justifications

- **The materials from which the stairs are made have constant mechanical properties and for the same material, the mechanical properties are consistent throughout the stairs.**

Explanation:Changes in the mechanical properties of materials over time or space will lead to increased complexity of analysis and difficulty in accurate modeling. Therefore, assuming that the material properties are constant and consistent can simplify the research process and improve the scientific and operability of the model.

- **The effect of special shoes such as high-heeled shoes on the wear of stairs is not considered in the analysis, and only the role of common soles is investigated.**

Explanation:The wear effect of special shoes such as high-heeled shoes is usually concentrated in localized areas and happens less frequently, which has a modest influence on the overall wear pattern.

- **The data obtained by the simulation expedition in the article is accurate and can truly reflect the wear of stairs and usage patterns.**

Explanation:Assumptions about the data that accurately reflect the wear of stairs and patterns of use will prevent data quality issues from interfering with the study.

- **The study was conducted only on uneven wear of stairs made of stone or wood due to long-term use.**

Explanation:The problem statement explicitly specifies that the study is limited to stone or wooden stairs that show uneven wear after long-term use.

- **All stair users walk at a normal gait (based on the first model, the “Human Gait Model”), and the effects of intentional friction or other abnormal use behaviors on the wear of stairs are not considered.**

Explanation:Assuming that all stair users walk at a normal gait allows the study to focus on regular use and natural wear and tear, thus simplifying the model and avoiding the introduction of unnecessary complexity due to unusual behaviors(such as intentional rubbing or fast running).

Additionally, to simplify the analysis, additional assumptions were introduced and are discussed in the relevant sections.

3 Notations

4 Model Preparation

4.1 Guidance on Obtaining Information

Before studying the wear of stairs, archaeologists must collect a variety of information about the target stairs to support subsequent modeling and analysis. This includes the following three components: measurement, literature search, and data preprocessing. 1.Measurement To ensure that the measurements are non-destructive, inexpensive, and can be done by a small number of people using minimal tools while maximizing the accuracy of the measurements, the following tools and measurement methods are chosen:

1.Measurement and data preprocessing of the depth of wear on stairs

Choose 20 steps of the target stairs and complete the following operations using the laser rangefinder and the vernier caliper for one steps:

- ★ Fix the laser range finder in a constant horizontal plane using a sliding table and set the height of the stair root as the reference height;
- ★ Randomly select 100 sample points for each square meter of the stair plane and record the 2D coordinates (x,y) of each sample point and its measured height.
- ★ Corners and other data that cannot be measured with a laser distance meter are measured with vernier calipers.

Next, based on the data obtained from the measurements, we can use the following formula to calculate the depth of wear for each sampling point:

$$\Delta h = h_{\text{sampling point}} - h_{\text{reference}}$$

All the $x, y, \Delta h$ data from the sampling points will be integrated to construct the subsequent ideal staircase wear model.

Step size measurement and data preprocessing

Randomly select 10 steps from the target staircase and use a meter rule to measure the length, width, and height of each step, record the data for each group and calculate the average to obtain the standard dimensions of the steps:

$$L_{\text{average}} = \frac{\sum_{i=1}^{10} L_i}{10}$$

$$W_{\text{average}} = \frac{\sum_{i=1}^{10} W_i}{10}$$

$$H_{\text{average}} = \frac{\sum_{i=1}^{10} H_i}{10}$$

2.Data Retrieval from Literature and Sources

The required information includes the construction and maintenance years, which can be determined through historical records or archaeological literature to estimate the approximate construction date and the timing of any renovations. Additionally, the material and mechanical properties of the staircase must be identified, either through a literature review or direct observation. Specifically, it is necessary to determine the primary material of the stairs and gather the following mechanical property parameters:

Table 1: Material Properties for Analysis

Property	Symbol
Elastic Modulus	E
Poisson Ratio	ν
Coefficient of Wear	k
Material Hardness	H

4.2 Step Load Interaction Model

To analyze the wear of stairs, it is essential to study how the force acts on the stairs when a person walks on them. Based on previous studies, we establish the Step Load Interaction Model (SLIM) to analyze the way forces act on stairs when a person walks on them. When a person walks on the stairs, the shoe is the only part that directly contacts the ground. Based on assumption n, without considering footwear such as high-heeled shoes, which significantly change the way the force acts, and neglecting the mass of the shoe itself, we can consider the force of the shoe on the ground to be equivalent to the force of the foot on the shoe. That is, under this simplified condition, the shoe does not affect the magnitude and distribution of the force.

By reviewing the literature, we obtained an Infrared pressure distribution diagram of the force on the foot when a person is walking up and down stairs^[2]. The blue part of this map indicates the minimum pressure and the orange and red parts indicate the maximum pressure. The parts with the highest pressure correspond to three parts of the foot, i.e. the Hallux region (first metatarsal), the Metatarsals two and three& the Metatarsals four and five regions, as well as the Medial and Lateral Calcaneus regions, which are defined as the main force-bearing areas. To further study the area of the main force-bearing areas and its relationship with the total area of the foot, we first outlined the projection profile of the foot with a black line on the infrared distribution map. Subsequently, the grid method was used to process the images: when a certain grid was covered by one-half or more of the image area, it was counted as one grid, otherwise, it was ignored.

Then, we counted 32 grids covered by the main force-bearing areas and 118 grids covered by the total projection of the foot, with the area share of the main stress portion being about 0.2712. Based on the average foot area of a U.S. citizen (approximately 245

Thus, we can abstract the force of the foot on the stairs to the action of the main force area.

According to the assumption n, the force exerted by a person walking on the stairs can be further simplified into the model shown in Figure n.

Figure n shows that a countertop of stairs can be divided into two parts: the actual footprint section and the weathering section. To simplify the model, we assume that all stepping occurs in the actual footprint section and analyze the wear only in this section in the formal modeling.

5 Synergizing Mechanics with Mathematical Modeling

5.1 Friction Model

The Mills model is used to characterize the wear of materials under multiple loading conditions and is suitable for complex wear scenarios by considering the microscopic changes in the material surface and its elastic recovery properties.

In the case of stairs, which are used under stable conditions (e.g., constant flow of people and gait characteristics), the friction process is dominated by sliding wear due to the low sliding velocities. In this case, the contact state of the stair surface (including pressure and temperature distribution) remains stable during the friction process. Based on this assumption, the amount of wear W is usually linearly related to the n th power of the sliding velocity V , where n is the velocity factor, which is related to the material properties and contact conditions

On this basis, to more accurately analyze the wear behavior of staircase materials (e.g., stone or wood), we will modify the classical Mills model and develop a mathematical model suitable for staircase wear analysis.

First, the normal load F acting on the surface of the staircase material is calculated with the following expression:

$$F(t) = \frac{F_q \cdot \mu}{1 + e^{t-e}}$$

Where F_q is the average value of normal pressure, μ represents the adjustment coefficient, and μ represents the coefficient of kinetic friction. The F obtained by Eq. n is used as an independent variable in the wear volume model to further calculate the material wear amount W :

$$W = \int_0^t \frac{K \cdot V^n \cdot F(t)}{H} dt$$

Where V represents the average sliding velocity of the contact producing friction, and K and H are the wear coefficient and hardness of the staircase material, respectively.

5.2 Bending Model

To describe the wear behavior of stairs more accurately, a mathematical model based on beam bending theory is developed to predict the wear under different conditions through the relationship between deflection and loading.

1. Variable description

- ✿ W_r : Deflection, the depth of deformation under external forces, measured in meters (m).
- ✿ ν : Poisson's ratio.
- ✿ k : Shear correction factor.
- ✿ q : Uniformly distributed load, measured in newtons per meter (N/m).
- ✿ E : Elastic modulus, measured in pascals (Pa).
- ✿ I : Moment of inertia of the stair cross-section, in meters to the fourth power (m⁴).
- ✿ A : Cross-sectional area of the stair, measured in square meters (m²).
- ✿ g : Gravitational acceleration, with a value of 9.98 meters per second squared (m/s²).
- ✿ X : Horizontal coordinate of the force application point, measured in meters (m).
- ✿ L : Total length of the beam model of the stair, measured in meters (m).

2. Coordinate axis description

The coordinate axis of the stair adopts the right-handed rectangular coordinate system, where the X-axis is along the horizontal direction of the stair, indicating the horizontal coordinates of the force position, and the Y-axis is along the vertical direction of the stair, indicating the change of deformation and deflection, and the origin of the coordinate system is located at the bottom of the stair, as illustrated in the figure n.

3. model building

Firstly, we simplify the stair to a model of a beam fixed at both ends (both ends are fixed by supports, one of which is supported with pulleys to allow sliding in the axial direction) [2][2]. Based on this assumption, the deflection equation for this model is expressed as:

$$W_r = \frac{9X}{24EI} \left[X^3 - 2LX^2 + L^3 - \frac{12EI}{kgA}(X - L) \right]$$

From the above equation, We established the functional relationship between the deflection W_r and the horizontal coordinate of the force application point X and plotted the corresponding figure n. The figure shows that the deflection reaches its maximum value near $X=X_{max}$.

We further abstracted the overall bending deformation of the stairs as a concave region centered at X_{max} , corresponding to the maximum deflection W_r . It is assumed that the cross-sectional profile of this region conforms to the shape of a catenary (while ignoring the deformation and concavity at other positions). The wear width of the catenary-shaped region is calculated using the following equation:

$$b = 2W_r \sinh\left(\frac{L}{2W_r}\right)$$

Through calculation, the wear width L_1 caused by each applied load is determined to be 0.1 ± 0.01 . For the sake of simplification in subsequent calculations, L_1 is treated as a constant value of 0.1.

6 Step-pit Model

To investigate the wear of stairs further, we first need to clarify the mechanical mechanism of human action on stairs during walking. To this end, this article developed the Step-pit model to quantify the wear and tear produced on the stairs by each step during walking.

1. Model preparation

Based on the SLIM, we have simplified the force exerted by a person walking on a stair. By analyzing the IR pressure distribution map using the grid method, the length and area of the foot as a whole and the three main force regions can be obtained as follows:

Where L_i represents the length of region i and S_i refers to the area of region i .

Then, coordinate axes are established on the profile of each step of the stairs, taking the i -th step as an example (as shown in Fig. n). According to relevant studies, the average step width of stairs is about 32.5 cm and the height is about 14.5 cm [2]

Using half the length of the grid edge in Figure n as a unit of measurement, therefore, the width of the stair treads is about 48 unit lengths and the height is about 21 unit lengths.

To ensure that the landing point always remains within the countertop of the stairs, their range of values must satisfy the following constraints (due to space limitations, only the coordinate range of point M is presented here. The coordinate ranges for points U and C will be derived and explained in detail later based on the relationships among the three points):

U: The pressure centers of Hallux

M: The pressure centers of Metatarsals Two and Three Metatarsals Four and Five

C: The pressure centers of Medial Calcaneus Lateral Calcaneus

This section sets the geometric foundation for the subsequent analysis and provides a rational coordinate frame.

2. Walking patterns and Landing point analysis

In this model, it is assumed that a person walks up and down stairs in two ways and only two ways:

- Full-foot Walking: The entire foot applies force to the stairs.
- Forefoot Walking: Only the forefoot region applies force, while the rear foot remains suspended in the air.

In addition, each individual used only one walking style during a complete flight of stairs. To standardize the analysis, M is used as a benchmark.

Calculation of standard coordinates

The standard coordinates on the $i+1$ st step can be obtained recursively from the standard coordinates of the i -th step: Although walking styles vary, regardless of the style, the human stride length tends to keep the landing point of the next step within a “comfort zone”. When the expected landing point is outside the comfort zone, the walker adjusts the stride length to bring it back within a reasonable

range. The comfort zone can be expressed as:

On this basis, the standard coordinates of the $i+1$ -th stair need to be adjusted according to the constraints of the comfort zone. The specific calculation process is shown in Figure N.

After multiple iterations, the model generates a probability distribution curve for the pressure in the second main stress area on the upper foot of the stair table surface (with respect to the variable x , see Fig. N for details).

Combining the coordinate relationships of the three main force regions, the probability distributions of the first and third force regions can be further plotted in Fig. N.

3. Wear depth analysis of a single step.

Literature ^[2] provides proportional relationships between the forces exerted by the three main force regions of the foot when a person walks on stairs. These ratios reflect the magnitude of the forces exerted on the stairs by the different regions. The results were plotted as a trilinear diagram below:

Where FG_i is the vertical pressure exerted by region i on the stairs and G is the total vertical pressure.

Assume that the wear volume can be approximated as a regular quadrangular pyramid, then based on its geometric characteristics, the wear depth in region m is calculated as:

Where W_m and S_m represent the wear volume and area of the m -th region, respectively.

The wear analysis of forefoot walking is similar to that of full-foot walking, but the proportional distribution of forces is different from that of full-foot walking due to the fact that there are only two main force regions applying forces. In Fig. N, a trilinear diagram was plotted to show the relationship between the force distribution in the two regions. The depth of wear was calculated in the same way as for full-footed walking, with only the parameters adjusted.

4. conclusion

7 MESH Analysis Model

To study stair wear due to friction when a person walks, MESH analysis model is constructed. A walkway width a person walks on stairs is at least equal to the average shoulder width (disregarding extreme crowding) and does not walk tightly against the edges of the stairs.

On this basis, we divide the plane of the staircase into several walkways, each with a width approximately equal to the average shoulder width. Multiple walks cover almost the entire width of the stairs, with the excess width evenly distributed between the left and right sides of the stairs in the direction of travel.

Delineation of the target area of the stairs

Combining the actual walking pattern, the force of human walking on stairs can be classified into the following four patterns:

To analyze the effect of walking patterns on the stairs more accurately, the actual stepping area at the intersection of each step of the stairs and the walkway is defined as the target area. In the plan view

of the stairs, the target areas are divided into four sub-areas, numbered 1, 2, 3, and 4, based on the functional characteristics of walking patterns (shown in Fig. n).

Sub-areas 1, 2, and 3: These areas correspond to the combined effects of different walking patterns, and their wears need to be analyzed separately according to the force characteristics of different patterns.

Sub-area 4: Located at the edge of the staircase, its influence is ignored in this study due to the large and rather small area affected by accidental factors.

With the above division, we clarify the force characteristics of different sub-regions by combining the four walking modes.

First, process the data measured by the archaeologists using the following formula:

$$X_1 = CE_1 - Wr^{\frac{35+28}{2}} \cdot (k_A + k_B + k_C + k_D)$$

$$X_2 = CE_2 - Wr^{\frac{24+34}{2}} \cdot (k_A + k_B + k_C + k_D)$$

$$X_3 = CE_3 - Wr^{\frac{12+23}{2}} \cdot (k_A + k_B + k_C + k_D)$$

$$X_4 = CE_4 - Wr^{\frac{6+11}{2}} \cdot (k_A + k_B + k_C + k_D)$$

$$X_5 = CE_5 - Wr^{\frac{3+5}{2}} \cdot (k_A + k_B + k_C + k_D)$$

Next, the force on each sub-region is quantitatively calculated using the relevant formulas:

$$X_1 = K_A \cdot A_{35 \rightarrow 38} - \alpha \quad (1)$$

$$X_2 = K_A \cdot A_{24 \rightarrow 24} + K_B \cdot B_{24 \rightarrow 34} - \alpha \quad (2)$$

$$X_3^* = K_A \cdot A_{12 \rightarrow 23} + K_C \cdot C_{12 \rightarrow 23} + K_D \cdot D_{12 \rightarrow 23} - \alpha \quad (3)$$

$$X_3^{**} = K_A \cdot A_{6 \rightarrow 11} + K_B \cdot B_{6 \rightarrow 11} + K_C \cdot C_{6 \rightarrow 11} + K_D \cdot D_{6 \rightarrow 11} - \alpha \quad (4)$$

$$X_3^{***} = K_A \cdot A_{3 \rightarrow 5} + K_B \cdot B_{3 \rightarrow 5} + K_C \cdot C_{3 \rightarrow 5} + K_D \cdot D_{3 \rightarrow 5} - \alpha \quad (5)$$

Where X_i represents the total depth of wear due to friction in sub-area i ; k refers to the number of people; $A_{i \rightarrow j}$ refers to the depth of friction due to friction at a time corresponding to the range of distance from the edge of the staircase from i to j ; and α is the amount of wear in the target area due to environmental factors (e.g., temperature changes, humidity fluctuations, extreme weather, etc.).

The formulae for subregions 1, and 2 have been given above, and since there is no direct function to calculate X_3 for subregion 3, Probability-based fitting method is designed to calculate the total depth of wear due to friction. The pseudo code is as follows:

8 Conclusion and Problem Solving

For Problem A

Initially, we assume that when only one person is walking on the stairs, the walkway selection for each step remains consistent, meaning they will walk along the same walkway throughout. Based on the formula n from the model and the results obtained from the pseudocode, we can derive the total number of people on each walkway as follows:

$$K_i = K_{Ai} + K_{Bi} + K_{Ci} + K_{Di}$$

Using this expression, we can calculate the total number of people on each path, which is then visually represented using a bar chart (as shown in Figure n).

After calculating the total number of people on each walkway, we further sum these values to obtain the total number of people using the stairs, expressed as:

$$K_{\text{total}} = \sum_{i=1}^n K_i$$

For Problem A:

The question of "How often were the stairs used?" is quantified as the average usage frequency of the stairs over the total usage time, with the calculation formula as follows:

$$\text{usage frequency} = \frac{K_{\text{total}}}{\text{total usage time}}$$

On this basis, the average time interval between uses of the stairs is obtained as

For Problem B:

The total number of people descending the stairs can be expressed as:

$$K_{\text{downstairs}} = K_B + K_D$$

The total number of people ascending the stairs can be expressed as:

$$K_{\text{upstairs}} = K_A + K_C$$

By comparing the total numbers of ascending and descending, We can draw the following conclusions regarding the direction of travel favored by the people using the stairs:

- If ..., it indicates that the travel direction favored by the people using the stairs is **ascending**.
- If ..., it indicates that the travel direction favored by the people using the stairs is **descending**.

For problem C: The Z-scores formula can be used to determine outliers in the data. When the Z_i corresponding to the i th data in a data set satisfies the condition $Z_i > 3.5^{[2]}$, it can be considered that there is a peak at that data point. The Z-scores formula is as follows:

$$Z_i = \frac{K_i - \bar{K}}{\sqrt{\text{Var}(K)}}$$

Where $\text{Var}(k)$ refers to the variance of the number of people on walkways and represents the mean value of the number of people on walkways.

The Z-scores formula can be used to determine whether a peak exists in the bar graph of the number of people on each walkway:

If a peak exists, it indicates that the number of people on a certain walkway is significantly higher than on other paths, suggesting that people tend to walk in a line;

If there is no peak, it indicates that the distribution of people across walkways is relatively uniform, suggesting that people prefer to walk side by side.

9 q

For Problem E

Based on the wear data shown in (Figure x), the wear in the 39-48 range is primarily influenced by environmental factors, exhibiting a mild weathering effect, and it is assumed that no significant wear is caused to the stairs.

On this basis, using the principles of probability theory, we can assume that the wear amount of the stairs caused each year follows a Gaussian distribution.

The total wear rate of the stairs is determined by both the average annual wear rate and the time (i.e., the number of years since construction), and their relationship is expressed as:

$$R_{\text{total}} = R_{\text{year}} \cdot T$$

Where R_{total} represents the total wear amount, R_{daily} is the annual wear amount, and T refers to the time span, which is the total number of years since the stairs were constructed.

Since division operations do not alter the distribution pattern of a Gaussian distribution, the estimated value of the construction year of the stairs also follows a Gaussian distribution. Therefore, we can further calculate the probability of the time period provided by the archaeologist within this estimated Gaussian distribution. The higher the probability, the more reliable the estimated value.

For Problem F

The primary method for repairing building materials involves reinforcing cracks by filling them with polymer materials^[2]. In addition, the steel plate bonding method is commonly used for strengthening flexural or tensile members (such as stair platform beams, platform slabs, and stair slabs) under normal working conditions and static loads. Closed protection by wrapping the original staircase components

in steel plates is also an option. For repairs or renovations that are visually apparent, their presence can typically be determined through direct observation. However, for polymer reinforcement methods that are not easily discernible to the naked eye, we have designed the following detection method:

We first calculate the difference between the measured original depth data of surface depressions and the optimized depth data from, identifying points with significant positive differences as abnormal depression points. These points may indicate abnormal depressions caused by repairs or renovations.

Next, we conduct secondary sampling on the treads where the abnormal depression points are located, significantly increasing the sampling density to 300 samples per square meter. The same abnormal point analysis is repeated on the newly collected data. If the newly identified abnormal points exhibit circular or strip-shaped clustered distributions (as shown in reference figures), we preliminarily conclude that the area may have undergone repairs using polymer reinforcement methods. To further verify the use of polymer materials for reinforcement, we employ the Torrent Permeability Test Method to measure the air permeability of the building material^[2]. Polymer materials typically exhibit strong adhesion, no powder residues, water resistance, and polishability. However, their air permeability differs significantly from that of the base stone material. By comparing air permeability values, we can further confirm the presence and extent of repaired regions.

When further analyzing areas with abnormal air permeability, we perform water absorption tests on the associated staircase treads. The specific method is as follows:

To further study areas with abnormal air permeability, we performed water absorption tests on the associated staircase treads. The specific steps are as follows:

Testing Procedure

1. Attach cobalt chloride test paper, fully saturated with water and turned pink, to both the clustered abnormal points and the normal areas of the staircase treads.
2. Cover the test paper with appropriately sized covers to prevent water evaporation.
3. Use a D345 camera to continuously monitor and record the color change of the test paper.

Analysis of Test Results

Cobalt chloride test paper turns blue upon water absorption. By monitoring the rate at which the paper turns blue, we can assess the water absorption capacity of different areas of the stone material. If the test paper in the clustered abnormal points turns blue at a delayed rate, it indicates poor water absorption capacity in that area, further supporting the conclusion that polymer reinforcement has been applied. Finally, by combining the test results with the surface water permeability characteristics of the material and comparing the water absorption differences between the clustered abnormal points and normal areas, the presence and spatial distribution of polymer material repairs can be further confirmed.

Through the above multi-level detection method, not only can the presence of repairs or renovations be scientifically determined, but the repaired areas can also be accurately identified.

For Problem G

To determine whether the source of the target material aligns with the archaeologist's hypothesis,

we recommend sampling from what the archaeologist believes to be the original source and conducting destructive mechanical experiments to obtain precise material parameters. These experimentally obtained parameters are then used to replace the tabulated values and are re-integrated into the Step-pit model to derive the optimal fitting result. Finally, this result is compared to the fitting result obtained using the tabulated parameters, with the coefficient of determination R^2 used as the evaluation criterion.

Goodness-of-fit calculation formula:

$$R^2 = \frac{SSR}{SST} = 1 - \frac{SSE}{SST}, \quad 0 \leq R^2 \leq 1$$

- The sum of Squares for Error (SSE): The sum of squared differences between the actual values and predicted values, reflecting the magnitude of errors.
- The sum of Squares for Regression (SSR): The sum of squared differences between the predicted values and the mean of the actual values, representing the variation explained by the model.
- The total Sum of Squares (SST): The sum of squared differences between the actual values and their mean, equivalent to the total variation. The relationship satisfies:

$$SST = SSE + SSR$$

R^2 represents the proportion of the total variation that can be explained by the model. The closer the R^2 value is to 1, the higher the consistency of the model. The R^2 value can be used to evaluate the match between the archaeologist's hypothesized material source and the actual results. When R^2 exceeds 0.8, it indicates that the source of the target material is consistent with the archaeologist's hypothesis.

For Problem H

Number of Users in a Typical Day for Staircase

In ... (referenced analysis), we have already obtained the total number of users during the operational period of the staircase. Assuming that the number of people using the stairs per day remains constant during this period, the number of people using the stairs in a typical day can be expressed as:

$$\text{Number of Users in a Typical Day} = \frac{\text{Total Number of Users}}{\text{Total Days of Usage}}$$

Short-Time High Traffic or Long-Time Low Traffic

Fatigue strength is significantly influenced by loading frequency, defined as the frequency at which force is applied to the material^{[?]. [?]. [?]}. Higher loading frequency accelerates the formation of micro-cracks within the material, which can rapidly propagate in a short period^{[?]. [?]}, ultimately leading to fracture. This indicates that higher loading frequencies directly increase the probability of fracture by expediting crack propagation. Consequently, when a large number of people use the staircase within

a short period, the increased loading frequency makes the formation and propagation of cracks within the staircase more likely, thereby increasing the risk of fracture.

Additionally, due to abrupt geometric transitions, the outer edges of staircases often exhibit stress concentration, which further accelerates fatigue damage. This stress concentration makes cracks more likely to propagate, ultimately resulting in material fracture. Observations of real structures corroborate this phenomenon, as cracks are predominantly concentrated along the outer edges of staircases, confirming the role of stress concentration.

In summary, when a large number of people use the staircase within a short period, the increased loading frequency and stress concentration at the outer edges are primary contributors to crack formation and propagation, ultimately leading to material damage and even fracture.

To quantify this effect, we evaluate the depression depth X_6 in the 0–3 step region of the staircase using the following equation:

$$\text{LFP} = X_6 - k_A A_{0-3} - k_B B_{0-3} - k_C C_{0-3} - k_D D_{0-3}$$

In cases of significant normal wear, the fracture risk in this region increases notably.

To assess the relationship between X_6 and the loading frequency parameter LFP, a Mann-Whitney U test is used. Since X_6 and $X_6 + \text{LFP}$ share similar data distributions and do not require identical distributions, the test is applied to determine whether $X_6 + \text{LFP}$ is significantly greater than X_6 . The hypotheses are as follows:

- Null Hypothesis (H_0): $X_6 + \text{LFP}$ is not significantly greater than X_6 .
- Alternative Hypothesis (H_1): $X_6 + \text{LFP}$ is significantly greater than X_6 .

The U statistic is calculated as follows:

$$U = n^2 + \frac{n}{2}(n+1) - R(X_6)$$

At a significance level of $\alpha = 0.05$, the rejection region is $U < 8$. The decision criteria are:

1.If $U < 8$, the alternative hypothesis H_1 is accepted, indicating material loss at the staircase edges caused by fractures.

2.If $U \geq 8$, the null hypothesis H_0 is accepted, suggesting that material loss at the staircase edges is primarily due to normal wear and bending, with no additional fractures.

Based on the Mann-Whitney U test results, the following conclusions can be drawn:

- If a significant difference exists between X_6 and LFP, it indicates that material loss at the staircase edges is not solely caused by normal wear and bending but is also due to a large number of people using the staircase in a short time.

- If no significant difference exists between X_6 and LFP, it indicates that a small number of people use the stairs over an extended time.

By integrating the Mann-Whitney U test results with the theoretical analysis, this method enables a reasonable determination of whether the staircase was used by a large number of people over a short time or by a small number of people over a long time.

10 Sensitivity Analysis

11 Strengths and Weaknesses

11.1 Strengths

11.2 Weaknesses

12 Conclusion
